XML Form Builder

Overview

The Islandora Form Builder (part of the XML Forms package) makes it possible for users to create, copy, and edit ingest forms, and to affiliate them with Content Models in the repository. The form definitions are defined in XML and stored in the Drupal Database.

Dependencies

Same as XML Forms package

- Islandora Core Module
- Tuque
- PHP Lib
- Objective Forms

Downloads

Part of XML Forms

Install

The module is installed as part of the XML Forms package

Usage

The form builder can be reached by going to Islandora > Form Builder (admin/islandora/xmlform).

From the main interface, users can:

- Remove a default form association
- Create a new form
- Import a form from an XML Form Definition
- Copy a form
- Edit a form
- View a form
- Export a form as an XML Form Definition
- Delete a custom form
- Associate a form with a content model

XML Form Edit GUI

This GUI models the XML Definition, allowing the user to add/remove/edit form elements, as well as change their order.

- Common Form Elements
  - Implemented by all elements.
XML CRUD Actions (Create, Read, Update, Delete)

Advanced Form Elements

- Only implemented by some elements.
- In most cases they will not be modified

XML CRUD Actions are very important. They define how to create/read/update/delete XML nodes using the form elements value and properties.

All actions define the Path and Path Context properties. These define where approximately in the XML document the action will be performed.

**Path** is an XPath that defines where the action will take place.

**Path Context** defines what context the path can be executed in. It can be one of three values:

1. **Document**: The XPath is executed at the root of the document.
2. **Parent**: The XPath is executed at its parents context. This is only valid if the form element is embedded in another form element like a tab panel or fieldset, and that tab panel or fieldset's Read action selected an XML node.
3. **Self**: The XPath is executed in the context selected by the Read action. This can be a bit tricky to understand. Read is the first action performed on the form element before rendering the element. It's used to populate the form element with a value. The node in which it gets its value from is set to be the Self context.

**XML Node Actions**

**Create**

- **Path**: XPath to the parent node where this new element will be inserted
- **Path Context**: The context in which Path is executed.
- **Schema**: The XPath to this element's definition.
- **Type**: One of three values: **Element**, **Attribute**, **XML**. This is the type of XML node that will be created. **XML** stands for a XML snippet.

**Element**

- **Value**: The name of the type to create if it is **Element** or **Attribute**. If it is **XML** then it will be a XML snippet where the form fields submitted value will replace `%value%` in the snippet.

**Read**

- **Path**: XPath to the element we want to use to populate this form field.
- **Path Context**: The context in which Path is executed.

**Update**

- **Path**: XPath to the element to update. This will often be `self::node()`.
- **Path Context**: The context in which Path is executed, this is often `self` which means it refers to the node selected by Read.
- **Schema**: Schema path to the elements definition, this is used for validating the submitted form values.

**Delete**

- **Path**: XPath to the element to delete. This will often be `self::node()`.
- **Path Context**: The context in which Path is executed. This is often `self` which means it refers to the node selected by Read.
